Synopsis

This user’s guide describes a level 4 MODIS land data product, MOD16, the global 8-day (MOD16A2) and annual (MOD16A3) terrestrial ecosystem Evapotranspiration (ET) dataset at 0.5 km spatial resolution over the 109.03 Million km2 global vegetated land areas designed for the MODIS sensor aboard the Aqua and Terra platforms. The MOD16 algorithm is based on the logic of the Penman-Monteith equation which uses daily meteorological reanalysis data and 8-day remotely sensed vegetation property dynamics from MODIS as inputs. This document is intended to provide both a broad overview and sufficient detail to allow for the successful use of the data in research and applications.

Please note the “MOD” prefix should be considered as referring to data sets derived from MODIS onboard either TERRA or Aqua satellite. That is, “MOD” in this document can also be treated as “MYD” derived from MODIS on Aqua.

1. The Algorithm, Background and Overview

Calculation of ET is typically based on the conservation of either energy or mass, or both. Computing ET is a combination of two complicated major issues: (1) estimating the stomatal conductance to derive transpiration from plant surfaces; and (2) estimating evaporation from the ground surface. The MOD16 ET algorithm runs at daily basis and temporally, daily ET is the sum of ET from daytime and night. Vertically, ET is the sum of water vapor fluxes from soil evaporation, wet canopy evaporation and plant transpiration at dry canopy surface. Remote sensing has long been recognized as the most feasible means to provide spatially distributed regional ET information on land surfaces. Remotely sensed data, especially those from polar-orbiting satellites, provide temporally and spatially continuous information over vegetated surfaces useful for regional measurement and monitoring of surface biophysical variables affecting ET, including albedo, biome type and leaf area index (LAI) (Los et al., 2000).

1.1 Energy Partitioning Logic

Energy partitioning at the surface of the earth is governed by the following three coupled equations:

\[ H = \rho c_p \frac{T_s - T_a}{r_a} \]  

\[ \lambda E = \frac{\rho c_p (e_{sat} - e)}{\lambda (r_a + r_s)} \]  

\[ A' = R_{net} - \Delta S - G = H + \lambda E \]  

where \( H, \lambda E \) and \( A' \) are the fluxes of sensible heat, latent heat and available energy for \( H \) and \( \lambda E \); \( R_{net} \) is net radiation, \( G \) is soil heat flux; \( \Delta S \) is the heat storage flux. \( \lambda \) is the latent heat of vaporization. \( \rho \) is air density, and \( c_p \) is the specific heat capacity of air; \( T_s, T_a \) are the
aerodynamic surface and air temperatures; \( r_a \) is the aerodynamic resistance; \( e_{sat} \), \( e \) are the water vapour pressure at the evaporating surface and in the air; \( r_s \) is the surface resistance to evapotranspiration, which is an effective resistance to evaporation from land surface and transpiration from the plant canopy. The psychometric constant \( \gamma \) is given by

\[
\gamma = \frac{C_p P_a M_a}{\lambda M_w}
\]

where \( M_a \) and \( M_w \) are the molecular masses of dry air and wet air respectively and \( P_a \) the atmospheric pressure.

1.2 Penman-Monteith Logic

Developing a robust algorithm to estimate global evapotranspiration is a significant challenge. Traditional energy balance models of ET require explicit characterization of numerous physical parameters, many of which are difficult to determine globally. For these models, thermal remote sensing data (e.g., land surface temperature, LST) are the most important inputs. However, using the 8-day composite MODIS LST (the average LST of all cloud-free data in the compositing window) (Wan et al., 2002) and daily meteorological data recorded at the flux tower, Cleugh et al. (2007) demonstrate that the results from thermal models are unreliable at two Australian sites (Virginia Park, a wet/dry tropical savanna located in northern Queensland and Tumbarumba, a cool temperate, broadleaved forest in south east New South Wales). Using a combination of remote sensing and global meteorological data, we have adapted the Cleugh et al. (2007) algorithm, which is based on the Penman–Monteith method and calculates both canopy conductance and ET. Monteith (1965) eliminated surface temperature from Equations (1) – (3) to give:

\[
\lambda E = \frac{s A' + \rho C_p \frac{(e_{sat} - e)}{r_a}}{s + \gamma \left(1 + \frac{r_s}{r_a}\right)} = \frac{s A' + \rho C_p \frac{VPD}{r_a}}{s + \gamma \left(1 + \frac{r_s}{r_a}\right)}
\]

where \( s = d(e_{sat})/dT \), the slope of the curve relating saturated water vapor pressure \( (e_{sat}) \) to temperature; \( A' \) is available energy partitioned between sensible heat and latent heat fluxes on land surface. \( VPD = e_{sat} - e \) is the air vapor pressure deficit. All inputs have been previously defined except for surface resistance \( r_s \), which is an effective resistance accounting for evaporation from the soil surface and transpiration from the plant canopy.

Despite its theoretical appeal, the routine implementation of the P-M equation is often hindered by requiring meteorological forcing data \( (A', T_a \text{ and } VPD) \) and the aerodynamic and surface resistances \( (r_a \text{ and } r_s) \). Radiation and soil heat flux measurements are needed to determine \( A' \); air temperature and humidity to calculate \( VPD \); and wind speed and surface roughness parameters to determine \( r_a \). Multi-temporal implementation of the P-M model at regional scales requires routine surface meteorological observations of air temperature, humidity, solar radiation and wind speed. Models for estimating maximum stomatal conductance including the effect of limited soil water availability and stomatal physiology requires either a fully coupled
biophysical model such as that by Tuzet et al. (2003) or resorting to the empirical discount functions of Jarvis (1976), which must be calibrated. Determining a surface resistance for partial canopy cover is even more challenging with various dual source models proposed (e.g. Shuttleworth and Wallace, 1985) to account for the presence of plants and soil.

2. The MOD16A2/MOD16A3 algorithm logic

MOD16 ET algorithm is based on the Penman-Monteith equation (Monteith, 1965) as in equation 5. Figure 2 shows the logic behind the improved MOD16 ET Algorithm for calculating daily MOD16 ET algorithm.

Figure 2. Flowchart of the improved MOD16 ET algorithm. LAI: leaf area index; FPAR: Fraction of Photosynthetically Active Radiation. Net radiation calculation and the use of FPAR are detailed in section 2.2.

2.1. Daytime and Nighttime ET

Daily ET should be the sum of daytime and nighttime ET. To separate daytime and nighttime ET, we first obtain their air temperature which will be used in the following sections to calculate the two ET components. To get nighttime average air temperature ($T_{night}$), we assume that daily average air temperature ($T_{avg}$) is the average of daytime air temperature ($T_{day}$) and $T_{night}$, and $T_{day}$ is the average of air temperature when downward solar radiation is above 0. Thus,

$$T_{night} = 2 * T_{day} - T_{day}$$
The net incoming solar radiation at night is assumed to be zero. Based on the optimization theory, stomata will close at night to prevent water loss when there is no opportunity for carbon gain (Dawson et al., 2007). In the improved ET algorithm, at night, the stomata are assumed to close completely and the plant transpiration through stomata is zero, except for the transpiration through leaf boundary-layer and leaf cuticles (more details in section 2.5). Both nighttime and daytime use the same ET algorithm except that different values at daytime and nighttime are used for the same variable.

2.2. Soil Heat Flux

In MOD16 ET algorithm, the net incoming radiation to the land surface ($R_{net}$) is calculated as the equations 7 and 8 (Cleugh et al., 2007).

$$R_{net} = (1 - a)R_{sl} + \sigma (\varepsilon_a - \varepsilon_s)(273.15 + T)^4$$  \hspace{1cm} (7)

$$\varepsilon_a = 1 - 0.26 \, e^{(7.77 \times 10^{-4}T^2)}$$

$$\varepsilon_s = 0.97$$

where $a$ is MODIS albedo, $R_{sl}$ is the downward shortwave radiation, $\varepsilon_s$ is surface emissivity, $\varepsilon_a$ is atmospheric emissivity, and $T$ is air temperature in °C. At daytime, if $R_{net}$ is less than zero, $R_{net}$ is set to be zero; at nighttime, if $R_{net}$ is less than -0.5 times of daytime $R_{net}$, nighttime $R_{net}$ is set as -0.5 multiplying daytime $R_{net}$. There is no soil heat flux ($G$) interaction between the soil and atmosphere if the ground is 100% covered with vegetation. Energy received by soil is the difference between the radiation partitioned on the soil surface and soil heat flux ($G$).

$$A = R_{net}$$  \hspace{1cm} (8)

$$A_c = F_c A$$

$$A_{soil} = (1 - F_c) A - G$$

where $A$ is available energy partitioned between sensible heat, latent heat and soil heat fluxes on land surface; $R_{net}$ is the net incoming radiation received by land surface; $A_c$ is the part of $A$ allocated to the canopy and $A_{soil}$ is the part of $A$ partitioned on the soil surface. Net radiation is partitioned between the canopy and soil surface based on vegetation cover fraction ($F_c$), in order to reduce numbers of inputs from MODIS datasets and to simplify the algorithm, we use 8-day 0.5 km² MOD15A2H FPAR (the Fraction of Absorbed Photosynthetically Active Radiation) as a surrogate of vegetation cover fraction (Los et al., 2000), $F_c = FPAR$.

At the extremely hot or cold places or when the difference between daytime and nighttime temperature is low (<5°C), there is no soil heat flux. The soil heat flux is estimated as:

$$G_{soil} = \begin{cases} 
4.73 \, T_i - 20.87 & T_{min\, close} \leq T_{avg} < 25°C, T_{day} - T_{night} \geq 5°C \\
0 & T_{avg} \geq 25°C \text{ or } T_{avg} < T_{min\, close} \text{ or } T_{day} - T_{night} \geq 5°C \\
0.39 A_i & \text{abs}(G_{soil}) > 0.39 \, \text{abs}(A_i)
\end{cases}$$
\[ G = G_{\text{soil}}(1 - F_c) \]  

where \( G_{\text{soil}} \) stands for the soil heat flux when \( F_c = 0 \); \( T_{\text{avg}} \) is annual average daily temperature, and \( T_{\text{ave}} \) is the threshold value below which the stomata will close completely and halt plant transpiration (Table 3.2; Running et al., 2004; Mu et al., 2007; Mu et al., 2011). At daytime, \( G_{\text{soil \ day}} = 0.0 \) if \( \Delta_{\text{day}} - G_{\text{soil \ day}} < 0.0 \); at nighttime, \( G_{\text{soil \ night}} = \Delta_{\text{night}} + 0.5 \Delta_{\text{day}} \) if \( \Delta_{\text{day}} > 0.0 \) and \( \Delta_{\text{night}} - G_{\text{night}} < -0.5 \Delta_{\text{day}} \).

### 2.3. Wet Surface Fraction

In the MOD16 algorithm, ET is the sum of water lost to the atmosphere from the soil surface through evaporation, canopy evaporation from the water intercepted by the canopy, and transpiration from plant tissues (Fig. 2). The land surface is covered by the plant and the bare soil surface, and percentage of the two components is determined by \( F_c \). Both the canopy and the soil surface are partly covered by water under certain conditions. The water cover fraction \( (F_{\text{cover}}) \) is taken from the Fisher et al. (2008) ET model, modified to be constrained to zero when relative humidity (RH) is less than 70%:

\[
F_{\text{wet}} = \int_{RH}^{0} RH^4 \begin{cases} \text{RH} \leq 100\% & 70\% \leq RH \leq 100\% \\ \end{cases} \]  

where \( RH \) is relative humidity (Fisher et al., 2008). When \( RH \) is less than 70%, 0% of the surface is covered by water. For the wet canopy and wet soil surface, the water evaporation is calculated as the potential evaporation as described in the next sections (2.4 and 2.6).

### 2.4. Evaporation from Wet Canopy Surface

Evaporation of precipitation intercepted by the canopy accounts for a substantial amount of upward water flux in ecosystems with high LAI. When the vegetation is covered with water (i.e., \( F_{\text{wet}} \) is not zero), water evaporation from the wet canopy surface will occur. ET from the vegetation consists of the evaporation from the wet canopy surface and transpiration from plant tissue, whose rates are regulated by aerodynamics resistance and surface resistance.

The aerodynamic resistance \( (rhc, \text{ s m}^{-1}) \) and wet canopy resistance \( (rvc, \text{ s m}^{-1}) \) to evaporated water on the wet canopy surface are calculated as

\[
rhc = \frac{1}{gL_{\text{ch}}LAIF_{\text{wet}}} \]  
\[
rrc = \frac{\rho C_p}{4 \sigma (T_i + 273.15)^{\frac{5}{2}}} \]
where \( rhc \) (s m\(^{-1}\)) is the wet canopy resistance to sensible heat, \( rrc \) (s m\(^{-1}\)) is the resistance to radiative heat transfer through air; \( g_{ls} \) (s m\(^{-1}\)) is leaf conductance to sensible heat per unit LAI, \( g_{le wv} \) (m s\(^{-1}\)) is leaf conductance to evaporated water vapor per unit LAI, \( \sigma \) (W m\(^{-2}\) K\(^{-4}\)) is Stefan-Boltzmann constant.

Following Biome-BGC model (Thornton, 1998) with revision to account for wet canopy, the evaporation on wet canopy surface is calculated as

\[
\lambda E_{wet c} = \frac{s A_c + \rho C_p F_c \left( e_{sat} - e \right) rhc}{s + \rho C_p \frac{rvc}{rrc}} F_{wet} \tag{12}
\]

where the resistance to latent heat transfer (rvc) is the sum of aerodynamic resistance (rhrc) and surface resistance (rs) in equation 5.

2.5. Plant Transpiration

2.5.1. Surface Conductance to Transpiration

Plant transpiration occurs not only during daytime but also at nighttime. For many plant species, stomatal conductance\((G_s^1)\) decreases as vapor pressure deficit (VPD) increases, and stomatal conductance is further limited by both low and high temperatures (Jarvis, 1976; Sandford and Javis, 1986; Kawamitsu et al., 1993; Schulze et al., 1994; Leuning, 1995; Marsden et al., 1996; Dang et al., 1997; Oren et al., 1999; Xu et al., 2003; Misson et al., 2004). Because high temperatures are often accompanied by high VPDs, we have only added constraints on stomatal conductance for VPD and minimum air temperature ignoring constraints resulting from high temperature. Based on the optimization theory, stomata will close at night to prevent water loss when there is no opportunity for carbon gain (Dawson et al., 2007).

\[
G_s^1 \begin{cases} 
C_L m(T_{min}) m(VPD) r_{corr} & i = daytime \\
0 & i = nighttime 
\end{cases}
\tag{13}
\]

The components of each terms in the above equation is calculated as below

\[
r_{corr} = \frac{1}{101300 \left( \frac{T_i + 273.15}{293.15} \right)^{1.75}}
\]
\[ m(T_{\text{min}}) = \begin{cases} 
\frac{T_{\text{min}} - T_{\text{min close}}}{T_{\text{min open}} - T_{\text{min close}}} & \text{if } T_{\text{min}} \geq T_{\text{min open}} \\
0 & \text{if } T_{\text{min close}} < T_{\text{min}} < T_{\text{min close}} \\
1 & \text{if } T_{\text{min}} \leq T_{\text{min close}} 
\end{cases} \]

\[ m(\text{VPD}) = \begin{cases} 
\frac{\text{VPD}_{\text{close}} - \text{VPD}}{\text{VPD}_{\text{close}} - \text{VPD}_{\text{open}}} & \text{if } \text{VPD}_{\text{open}} < \text{VPD} < \text{VPD}_{\text{close}} \\
0 & \text{if } \text{VPD} \geq \text{VPD}_{\text{close}} 
\end{cases} \]

where \( C_L \) is the mean potential stomatal conductance per unit leaf area, \( C_L \) is set differently for different biomes as shown in Table 3.2 (Kelliher et al., 1995; Schulze et al., 1994; White et al., 2000), \( m(T_{\text{min}}) \) is a multiplier that limits potential stomatal conductance by minimum air temperatures \( (T_{\text{min}}) \), and \( m(\text{VPD}) \) is a multiplier used to reduce the potential stomatal conductance when \( \text{VPD} \) (difference between \( e_{\text{sat}} \) and \( e \)) is high enough to reduce canopy conductance. Sub index close indicates nearly complete inhibition (full stomatal closure) due to low \( T_{\text{min}} \) and high \( \text{VPD} \), and open indicates no inhibition to transpiration (Table 3.2). When \( T_{\text{min}} \) is lower than the threshold value \( T_{\text{min close}} \), or \( \text{VPD} \) is higher than the threshold \( \text{VPD}_{\text{close}} \), the strong stresses from temperature or water availability will cause stomata to close completely, halting plant transpiration. On the other hand, when \( T_{\text{min}} \) is higher than \( T_{\text{min open}} \), and \( \text{VPD} \) is lower than \( \text{VPD}_{\text{open}} \), there will be no temperature or water stress on transpiration. For \( T_{\text{min}} \) and \( \text{VPD} \) falling into the range of the upper and low limits, the corresponding multiplier will be within 0.0 to 1.0, implying a partial stomatal closure. The multipliers range linearly from 0 (total inhibition, limiting \( r_c \)) to 1 (no inhibition) for the range of biomes are listed in a Biome Properties Look-Up Table (BPLUT) (Table 3.2).

The reason we use the correction function \( r_{\text{corr}} \) for calculation of stomatal conductance is that, the conductance through air varies with the air temperature and pressure. The prescribed values are assumed to be given for standard conditions of 20° C and 101300 Pa. Based on the prescribed daily air temperature (converted to Kelvins) and an air pressure estimated from a prescribed elevation, the prescribed standard conductances are converted to actual conductances for the day according to Jones (1992) and Thornton (1998). \( P_a \) is calculated as a function of the elevation (Thornton, 1998).

\[
\begin{align*}
t_1 &= 1 - \frac{LR_{\text{STD} \ E elev}}{T_{\text{STD}}}
\end{align*}
\]

\[
\begin{align*}
t_2 &= 1 - \frac{LR_{\text{STD} \ RR \ MA}}{G_{\text{STD}}}
\end{align*}
\]

\[
P_a = P_{\text{STD}} \ t_1 \ t_2
\]

where \( LR_{\text{STD}}, T_{\text{STD}}, G_{\text{STD}}, RR, MA \) and \( P_{\text{STD}} \) are constant values as listed in Table 1.1 \( LR_{\text{STD}} \) (K m\(^{-1}\)) is standard temperature lapse rate; \( T_{\text{STD}} \) (K) is standard temperature at 0.0 m elevation; \( G_{\text{STD}} \) (m s\(^{-2}\)) is standard gravitational acceleration; \( RR \) (m\(^{\SI{}{\cdot}}\) Pa mol\(^{-1}\) K\(^{-1}\)) is gas law constant; \( MA \) (kg mol\(^{-1}\)) is molecular weight of air and \( P_{\text{STD}} \) (Pa) is standard pressure at 0 m elevation.

Canopy conductance ($C_c$) to transpired water vapor per unit LAI is derived from stomatal and cuticular conductances in parallel with each other, and both in series with leaf boundary layer conductance (Thornton, 1998; Running & Kimball, 2005). In the case of plant transpiration, surface conductance is equivalent to the canopy conductance ($C_c$), and hence surface resistance ($r_s$) is the inverse of canopy conductance ($C_c$).

$$C_{c_i} = \begin{cases} \frac{G^2_s (G^1_s + G_{CU})}{G^1_s + G^2_s + G_{CU}} & (LAI > 0, (1 - F_{wet}) > 0) \\ 0 & (LAI = 0, (1 - F_{wet}) = 0) \end{cases} \quad (15)$$

$$G_{cu} = g_{cu} r_{corr}$$

$$G^2_s = g_{lsh}$$

$$r_{s_i} = \frac{1}{C_{c_i}}$$

where the subscript $i$ means the variable value at daytime and nighttime; $G_{CU}$ is leaf cuticular conductance; $G^2_s$ is leaf boundary-layer conductance; $g_{cu}$ is cuticular conductance per unit LAI, set as a constant value of 0.00001 (m s$^{-1}$) for all biomes; $g_{lsh}$ is leaf conductance to sensible heat per unit LAI, which is a constant value for each given biome (Table 3.2).

### 2.5.2. Aerodynamic Resistance

The transfer of heat and water vapor from the dry canopy surface into the air above the canopy is determined by the aerodynamic resistance ($r_a$). $r_a$ is calculated as a parallel resistance to convective ($r_h$) and radiative ($r_r$) heat transfer following Biome-BGC model (Thornton, 1998).

$$r_a = \frac{r_h r_r}{r_h + r_r}$$

$$r_h = \frac{1}{g_{l_{bl}}}$$

$$r_r = \frac{\rho C_p}{4 \sigma (T_i + 273.15)^3}$$

where $g_{l_{bl}}$ (m s$^{-1}$) is leaf-scale boundary layer conductance, whose value is equal to leaf conductance to sensible heat per unit LAI ($g_{lsh}$ (m s$^{-1}$) as in section 2.4), and $\sigma$ (W m$^{-2}$ K$^{-4}$) is Stefan-Boltzmann constant.

### 2.5.3. Plant Transpiration

Finally, the plant transpiration ($AE_{trans}$) is calculated as
\[ \lambda E_{\text{trans}} = \frac{(s A_c + \rho C_p F_c \left( \frac{e_{\text{sat}} - e}{r_a} \right))(1 - F_{\text{wet}})}{s + \gamma \left( 1 + \frac{r_s}{r_a} \right)} \]  

where \( r_a \) is the aerodynamic resistance calculated from equation 5.

\[ \lambda E_{\text{pot trans}} = \frac{\alpha s A_c (1 - F_{\text{wet}})}{s + \gamma} \]  

with \( \alpha = 1.26 \).

### 2.6. Evaporation from Soil Surface

The soil surface is divided into the saturated surface covered with water and the moist surface by \( F_{\text{wet}} \). The soil evaporation includes the potential evaporation from the saturated soil surface and evaporation from the moist soil surface. The total aerodynamic resistance to vapor transport (\( r_{\text{tot}} \)) is the sum of surface resistance (\( r_s \)) and the aerodynamic resistance for vapor transport (\( r_v \)) such that \( r_{\text{tot}} = r_v + r_s \) (van de Griend & Owe, 1994; Mu et al., 2007). We assume that \( r_v = r_s \) (\( m^{-1} \)) is equal to the aerodynamic resistance (\( r_a \)) in Equation 5 since the values of \( r_v \) and \( r_a \) are usually very close (van de Griend & Owe, 1994). In the MOD16 ET algorithm, the \( rhs \) is assumed to be equal to boundary layer resistance, which is calculated in the same way as total aerodynamic resistance (\( r_{\text{tot}} \)) (Thornton, 1998) only that, \( r_{\text{tot}} \) is not a constant. For a given biome type, there is a maximum (\( r_{\text{bl,max}} \)) and a minimum value (\( r_{\text{bl,min}} \)) for \( r_{\text{tot}} \), and \( r_{\text{tot}} \) is a function of VPD.

\[ r_{\text{tot}} = r_{\text{totc}} r_{\text{corr}} \]  

\[ r_{\text{totc}} = \begin{cases} 
  r_{\text{bl,max}} & \text{VPD} \leq VPD_{\text{open}} \\
  r_{\text{bl,max}} - \frac{(r_{\text{bl,max}} - r_{\text{bl,min}})(VPD_{\text{close}} - VPD)}{VPD_{\text{close}} - VPD_{\text{open}}} & VPD_{\text{open}} < VPD < VPD_{\text{close}} \\
  r_{\text{bl,min}} & VPD \geq VPD_{\text{close}} 
\end{cases} \]

where \( r_{\text{corr}} \) is the correction for atmospheric temperature and pressure (equation 13) above mentioned. The values of \( r_{\text{bl,max}} \) and \( r_{\text{bl,min}} \), \( VPD_{\text{open}} \) (when there is no water stress on transpiration) and \( VPD_{\text{close}} \) (when water stress causes stomata to close almost completely, halting plant transpiration) are parameterized differently for different biomes and are listed in Table 3.2.

The aerodynamic resistance at the soil surface (\( r_{\text{as}} \)) is parallel to both the resistance to convective heat transfer (\( rhs \): \( m^{-1} \)) and the resistance to radiative heat transfer (\( r_{\text{rs}} \): \( m^{-1} \)) (Choudhury and DiGirolamo, 1998), such that

\[ r_{\text{as}} = \frac{r_{\text{hs}} r_{\text{rs}}}{r_{\text{hs}} + r_{\text{rs}}} \]

\[ r_{\text{hs}} = r_{\text{tot}} \]

\[ r_{\text{rs}} = \frac{\rho C_p}{4 \sigma (T_i + 273.15)^3} \]
The actual soil evaporation ($\lambda E_{\text{soil}}$) is calculated in equation 21 using potential soil evaporation ($\lambda E_{\text{soil,pot}}$) and soil moisture constraint function in the Fisher et al. (2008) ET model. This function is based on the complementary hypothesis (Bouchet, 1963), which defines land-atmosphere interactions from air VPD and relative humidity (RH, %).

$$\lambda E_{\text{soil,pot}} = \left( s A_{\text{soil}} + \rho C_p (1 - F_c) \frac{VPD}{r_{as}} \right) \left( s + \gamma \frac{r_{tot}}{r_{as}} \right)$$

$$\lambda E_{\text{soil}} = \lambda E_{\text{soil,pot}} + \lambda E_{\text{wet,soil}} (RH)$$

with $\beta = 200$.

### 2.7. Total Daily Evapotranspiration

The total daily ET is the sum of evaporation from the wet canopy surface, the transpiration from the dry canopy surface and the evaporation from the soil surface. The total daily ET and potential ET ($\lambda E_{\text{pot}}$) are calculated as in equation 22.

$$\lambda E = \lambda E_{\text{wet,c}} + \lambda E_{\text{trans}} + \lambda E_{\text{soil}}$$

$$\lambda E_{\text{pot}} = \lambda E_{\text{wet,c}} + \lambda E_{\text{pot,trans}} + \lambda E_{\text{wet,soil}} + \lambda E_{\text{soil,pot}}$$

Combination of ET with the potential ET can determine environmental water stress and detect the intensity of drought.

### 2.8. Updates after Publication of RSE Paper by Mu et al. (2011)

The MOD16 products are generated based on the MOD16 algorithm in Mu et al.'s 2011 RSE paper. Since the publication, Dr. Mu have updated the product to fix some issues and these updates have been implemented in the operational code.

1. **Issue of negative ET and PET values for some 8-day and monthly data.**

   In the previous product, we allowed the net incoming daytime radiation to be negative. Only MERRA daytime downward solar radiation, daytime actual vapor pressure, daytime temperature, daily average and minimum temperatures are used as meteorological inputs. The outgoing and incoming longwave radiation is calculated as in Mu et al.'s 2011 RSE paper. In the updated product, the nighttime actual vapor pressure, nighttime temperature, outgoing and incoming longwave radiation are from MERRA directly. If daytime $R_{net} < 0$; daytime $R_{net} = 0$.

   In the MOD16 ET algorithm, when we calculated the soil heat flux, we didn't constrain the soil heat flux. The net radiation to the bare ground is difference between the fraction of the net incoming radiation reaching to the ground surface ($R_{ground}$) and the soil heat flux ($G$). In
certain cases, G is higher than R_{ground}, resulting in negative soil evaporation. In the updated product, we set limit to G. For daytime R_{net} and G:

$$if \ (R_{net} - G) < 0; \ G = R_{net}$$

Whereas for nighttime R_{net} and G:

$$if \ (R_{net} - G) < -0.5 \cdot \text{daytime} \ R_{net}; \ G = R_{net} + 0.5 \cdot \text{daytime} \ R_{net}$$

2. Issue of no valid MODIS surface albedo values throughout the year for vegetated pixels due to high frequency of cloudiness.

In the improved MOD16. For example, no single valid MODIS albedo can be found throughout an entire year over rainforests of west Africa due to severe and constant cloudiness. In the update version, we specify an albedo value of 0.4 for the pixels, a typical value for nearby rainforests with valid albedo values.

3. Operational Details of MOD16 and Primary Uncertainties in the MOD16 Logic

A number of issues are important in implementing this algorithm. This section discusses some of the assumptions and special issues involved in development of the input variables, and their influence on the final ET estimates.

3.1. Dependence on MODIS Land Cover Classification MCDLCHKM

![Figure 3.1](image)

*Figure 3.1. Collection5 1-km MODIS ET used land cover type 2 in 1-km Collection4 MOD12Q1 dataset. Whereas Collection6 operational 500-m MODIS ET is using land cover type 1 in Collection5.1 500-m MCDLCHKM which is a 3-year smoothed MODIS land cover data set. This figure shows land cover types from the Collection4 MOD12Q1 dataset: Evergreen Needleleaf Forest (ENF), Evergreen Broadleaf Forest (EBF), Deciduous Needleleaf Forest (DNF), Deciduous Broadleaf Forest (DBF), Mixed forests (MF), Closed Shrublands (CShrub), Open Shrublands (OShrub), Woody Savannas (WSavanna), Savannas (Savanna), grassland (Grass), and Croplands (Crop). Note that in this figure, we combined CShrub and OShrub into*
Shrub, and WSavanna and Savannas into Savanna. Globally, Collection5.1 500-m MCDLCHKM has a similar spatial pattern to this image.

One of the first MODIS products used in the MOD16 algorithm is the Land Cover Product. For the previous Collection5 1-km MODIS ET, the 1-km land cover type 2 in a frozen version of the Collection4 MOD12Q1 was used. However, for the operational Collection 6 500-m MODIS ET, a 3-year smoothed land cover data set, land cover type 1 in the Collection5.1 500-m MCDLCHKM, is being used. The importance of this product cannot be overstated as the MOD16 algorithm relies heavily on land cover type through use of the BPLUT. The land cover type 1 created by 500-m MCDLCHKM is a 17-class IGBP (International Geosphere-Biosphere Programme) land cover classification map (Running et al. 1994, Belward et al. 1999, Friedl et al. 2010) (Table 3.1). Figure 3.1 shows the Collection4 1-km MOD12Q1 dataset used by the Collection5 MODIS ET. Globally, Collection5.1 500-m MCDLCHKM has a very similar spatial pattern to this image though it may have a different land cover type for a given pixel.

3.1.1. The BPLUT and constant biome properties

Arguably, the most significant assumption made in the MOD16 logic is that biome-specific physiological parameters do not vary with space or time. These parameters are outlined in the BPLUT (Table 3.2) within the MOD16 algorithm. The BPLUT constitutes the physiological framework for controlling simulated ET. These biome-specific properties are not differentiated for different expressions of a given biome, nor are they varied at any time during the year. In other words, a semi-desert grassland in Mongolia is treated the same as a tallgrass prairie in the Midwestern United States. Likewise, a sparsely vegetated boreal evergreen needleleaf forest in Canada is functionally equivalent to its coastal temperate evergreen needleleaf forest counterpart.

3.2 Leaf area index, fraction of absorbed photosynthetically active radiation and albedo

The FPAR/LAI product is an 8-day composite product. The MOD15 compositing algorithm uses a simple selection rule whereby the maximum FPAR (across the eight days) is chosen for the inclusion as the output pixel. The same day chosen to represent the FPAR measure also contributes the current pixel’s LAI value. This means that although ET is calculated daily, the MOD16 algorithm necessarily assumes that leaf area and FPAR do not vary during a given 8-day period. Compositing of LAI and FPAR is required to provide an accurate depiction of global leaf area dynamics with consideration of spectral cloud contamination, particularly in the tropics.

The MCD43A2/A3 albedo products are 16-day moving daily products too. Both Terra and Aqua data are used in the generation of this product, providing the highest probability for quality input data and designating it as an "MCD," meaning "Combined," product. Version-6 MODIS/Terra+Aqua BRDF/Albedo products are Validated Stage 1, indicating that accuracy has been estimated using a small number of independent measurements obtained from selected locations and time periods and ground-truth/field program efforts. Although there may be later improved versions, these data are ready for use in scientific publications.

3.2.1. Additional Cloud/Aerosol Screening

The 8-day MOD15A2H and daily MCD43A3 are still contaminated by clouds and/or aerosols in certain regions and times of year. As a result, in regions with higher frequencies of cloud cover, such as tropical rain forests, values of FPAR and LAI will be greatly reduced and the albedo signal dramatically increased. To distinguish between good quality and contaminated data, MOD15A2H and MCD43A3 contain Quality Control (QC) fields, enabling users to determine which pixels are suitable for further analysis. The use of contaminated FPAR, LAI or albedo inputs will produce incorrect ET estimates. Thus for NASA’s operational MOD16 dataset, users should be cautious when use the data and contaminated MOD16 data sets should be excluded from analysis. In this case, QC data field should be used to distinguish uncontaminated or unreliable MOD16 pixels for the same data period. Only for the reprocessed and improved MOD16, users may ignore QC because the contaminated MODIS inputs to MOD16 have been temporally filled, resulting in an improved MOD16. The following describes the method we employed for the improved MOD16.

\[ \text{The following screening and gap-filling processes are only applied to the improved MOD16.} \]

\[ \text{In the early of each year when the previous full yearly MOD15A2H/MCD43A3 are available for reprocess (also see section 6.3).} \]

To improve the MOD16 data product, we solved this problem related to MOD15A2H/MCD43A3 inputs by removing poor quality FPAR/LAI/Albedo data based on the QC label for every pixel. If, for example, any LAI/FPAR pixel did not meet the quality screening criteria, its value is determined through linear interpolation between the previous period’s value and that of the next period to pass the screening process. Contaminated MOD15A2H/MCD43A3 was improved as the result of the filling process. However, there are some unusual 8-day periods with lower FPAR and LAI but good QC labels. In spite of this, we have to depend on QC label
because this is the only source of quality control. Improved MOD15A2H/MCD43A3 leads to improvements of MOD16.

### 3.3. GMAO daily meteorological data

The MOD16 algorithm computes ET at a daily time step. This is made possible by the daily meteorological data, including average and minimum air temperature, incident PAR and specific humidity, provided by NASA’s Global Modeling and Assimilation Office (GMAO or MERRA GMAO), a branch of NASA (Schubert et al. 1993). These data, produced every six hours, are derived using a global circulation model (GCM), which incorporates both ground and satellite-based observations. These data are distributed at a resolution of 0.5° x 0.6° (MERRA GMAO) or 1.00° x 1.25° (note that resolution may become finer with updates of GMAO system at NASA) in contrast to the 0.5 km gridded MOD16 outputs. It is assumed that the coarse resolution meteorological data provide an accurate depiction of ground conditions and are homogeneous within the spatial extent of each cell.

One major problem is the inconsistency in spatial resolution between half-degree GMAO/NASA meteorological data and 0.5 km MODIS pixel. We solved the problem by spatially smoothing meteorological data to 0.5 km MODIS pixel level. For the problem arising from coarse spatial resolution daily GMAO data, we use spatial interpolation to enhance meteorological inputs. The four GMAO cells nearest to a given 0.5 km MODIS pixel are used in the interpolation algorithm. There are two reasons for choosing four GMAO cells per 0.5 km MODIS pixel: (1) this will not slow down the computational efficiency of creating MOD16, which is a global product, and (2) it is more reasonable to assume no elevation variation within four GMAO cells than more GMAO cells.

Although there are many formulae for non-linear spatial interpolation, for simplicity, we use a cosine function because the output value can be constrained between 0 and 1. This function still could not effectively boundary lines in a MOD16 image, and thus we utilized a modified cosine function of the form:

\[
D_i = \cos^4 \left( \frac{\pi}{2} \left( \frac{d_i}{d_{\max}} \right) \right), \quad i = 1, 2, 3, 4
\]

where, \( D_i \) is the non-linear distance between the 0.5 km MODIS pixel and any one of four surrounding GMAO cells; \( d_i \) is the great-circle distance between the 0.5 km pixel and the same GMAO cell; and \( d_{\max} \) is the great-circle distance between the two farthest GMAO cells of the four being used. This ensures that \( D_i = 1 \) when \( d_i = 0 \), and \( D_i = 0 \) when \( d_i = d_{\max} \).

Based on the non-linear distance \( (D_i) \), the weighted value \( W_i \) can be expressed as

\[
W_i = D_i / \sum_{i=1}^{4} D_i,
\]

and therefore, for a given pixel, the corresponding smoothed value \( V \) (i.e., interpolated Tmin, Tavg, VPD, SWrad) is
\[ V = \sum_{i=1}^{4} (W_i V_i) \]  

Theoretically, this GMAO spatial interpolation can improve the accuracy of meteorological data for each 0.5 km pixel because it is unrealistic for meteorological data to abruptly change from one side of GMAO boundary to the other. To explore the above question, we use observed daily weather data from World Meteorological Organization (WMO) daily surface observation network (>5000 stations) to compare changes in Root Mean Squared Error (RMSE) and Correlation (COR) between the original and enhanced DAO data. As a result of the smoothing process, on average, RMSE is reduced and COR increased for 72.9% and 84% of the WMO stations, respectively, when comparing original and enhanced DAO data to WMO observations for 2001 and 2002. Clearly, the nonlinear spatial interpolation significantly improves GMAO inputs for most stations, although for a few stations, interpolated GMAO accuracy may be reduced due to the inaccuracy of GMAO in these regions. (Zhao et al. 2005, 2006)

4. Validation of MOD16

To validate the MOD16 algorithm, we used the observed latent heat flux for 46 field-based eddy covariance flux towers, global 232 watersheds, as well as global results over the past 11 years (2000 to 2010). We cut out the input MODIS data for the 3 x 3 1-km² pixels surrounding each tower. We drove the MOD16 ET algorithm with both tower observed meteorological data and global GMAO meteorological data. We got the average ET estimates over those of the 3 x 3 1-km² pixels where the tower actual vegetation type is the same as MODIS land cover. Then we compared the ET estimates with the tower ET observations. For each of the seven biome types among the 46 flux towers except for CSH and OSH since there is only one tower with fewer than 365 measurements for each of them, we chose one tower to show the performance of MOD16 ET algorithm (Fig. 4.1).

![Figure 4.1](image-url)  

*Figure 4.1.* The ET measurements (black dots, OBS), the ET estimates driven by flux tower measured meteorological data (red lines) and GMAO meteorological data (blue lines) over 2000-2006 at seven tower sites, Donaldson (a) and LBA Tapajos KM67 Mature Forest (b).
The average daily ET biases between ET observations and ET estimates across the 46 towers are -0.11 kg/m²/day driven by tower meteorological data and -0.02 kg/m²/day driven by GMAO meteorological data. The average mean absolute errors (MAE) are 0.33 kg/m²/day (tower-specific meteorology) and 0.31 kg/m²/day (GMAO meteorology). The MAE values are 24.6% and 24.1% of the ET measurements, within the 10-30% range of the accuracy of ET observations (Courault et al. 2005; Jiang et al. 2004; Kalma et al. 2008).

5. Practical Details for downloading MOD16 Data

All MODIS land data products are distributed to global users from the USGS Land Processes Distributed Active Archive Center (USGS LP DAAC), found here:

https://lpdaac.usgs.gov/

Specific details about the MODIS land products can be found here:

https://lpdaac.usgs.gov/dataset_discovery/modis

including details about sensor spectral bands, spatial/temporal resolution, platform overpass timing, datafile naming conventions, tiling formats, processing levels and more.

When this document is being written, MODAPS at NASA is testing the operational Collection6 MOD16 code and 500m MOD16 data will be released to the public through the USUS LP DAAC soon (https://lpdaac.usgs.gov/data_access).

The long-term consistent improved global Collection5 1-km MOD16 from year of 2000 to the previous year can be downloaded at NTSG at site

http://www.ntsg.umt.edu/project/mod16#data-product

6. MOD16 Data Description and Process

6.1. Description and Process of MOD16 Data Files

There are two major MOD16 data sets, 8-day composite MOD16A2 and annual composite MOD16A3. Both MOD16A2 and MOD16A3 are stored in HDFEOS2 scientific data file format (http://hdfeos.org/software/library.php). HDFEOS2 file format is an extension of HDF4 by adding geo-reference, map projection, and other key meta data information to HDF4 format (https://support.hdfgroup.org/products/hdf4/) to facilitate users to use satellite data products from NASA’s Earth Observing System (EOS) projects. Since MOD16 is a level 4 EOS data product, the grid data sets are saved in Sinusoidal (SIN) map projection, an equal-area map projection, with an earth radius of 6371007.181 meters (Note the inversed lat/lon are in WGS84 datum). The MODIS high-level data sets divide the global SIN into many chunks, so-called 10-degree tiles (https://modis-land.gsfc.nasa.gov/MODLAND_grid.html). There are 317 land tiles, and among which, 300 tiles (286 tiles for the Collection5) located within latitude of 60°S and 90°N (90°N for the Collection5) have vegetated land pixels. Therefore, for each 8-day
Collection6 MOD16A2 and yearly MOD16A3, there are 300 land tiles globally if there are no missing tiles.

When MODIS updates MOD16 from the Collection5 to Collection6, the spatial resolution has increased from nominal 1-km (926.6254313883 meters) to 500m (463.31271669415 meters), to be consistent with changes in the spatial resolution of a major input to MOD16, the 8-day MOD15A2H.

For users don’t know how to handle and process MODIS high-level data products, we suggest users use free or commercial software tools, such as MODIS Reprojection Tool (MRT) (https://lpdaac.usgs.gov/tools/modis_reprojection_tool ), HDF-EOS to GeoTIFF Conversion Tool (HEG) (http://hdfeos.org/software/heg.php ), or MODIS toolbox in ArcMap (https://blogs.esri.com/esri/arcgis/2011/03/21/global-evapotranspiration-data-accessible-in-arcmap-thanks-to-modis-toolbox/) to handle MOD16.

6.2. Description of MOD16 Date Sets

6.2.1. MOD16A2

Table 6.1 lists science data sets in the 8-day MOD16A2. ET_500m and potential ET (PET), PET_500m, are the summation of 8-day total water loss through ET (0.1 kg/m²/8day), whereas the associated latent heat fluxes and its potential, LE_500m and PLE_500m, are the average total energy over a unit area for a unit day during the composite 8-day period (10000 J/m²/day). But be cautious that the last 8-day (MOD16A2.A20??361.*.hdf) of each year is not 8-day but either 5-day or 6-day depending on normal or leap year.

As listed in Table 6.1, for valid data (Valid_data with the valid range) of MOD16A2, the real value (Real_value) of each data set (ET, LE, PET or PLE) in the corresponding units (kg/m²/8d or J/m²/d) can be calculated using the following equation,

\[
\text{Real_value} = \text{Valid_data} \times \text{Scale_Factor}
\]

Table 6.1. The detailed information on science data sets in MOD16A2

<table>
<thead>
<tr>

</tr>
</tbody>
</table>

All data sets in MOD16A2, except Quality Control (QC) data field, ET_QC_500m, have valid value ranging from -32767 to 32760 and are saved in signed 2-byte short integer (int16). Though data attributes list just one _FillValue: 32767 in the head file of MOD16A2 file, there are, in fact, 7 fill values listed below for non-vegetated pixels, which we didn’t calculate ET.
32767 = _Fillvalue
32766 = land cover assigned as perennial salt or Water bodies
32765 = land cover assigned as barren, sparse veg (rock, tundra, desert)
32764 = land cover assigned as perennial snow, ice.
32763 = land cover assigned as "permanent" wetlands/inundated marshland
32762 = land cover assigned as urban/built-up
32761 = land cover assigned as "unclassified" or (not able to determine)

The QC data layer, ET_QC_500m, directly inherits the QC data field, FparLai_QC, from the corresponding MOD15A2 of the same 8-day. Detailed information of bitfields in 8 bitword is the same as that from MOD15A2, as detailed below.

Data Field Name: ET_QC_500m

BITS BITFIELD
-------------
0,0 MODLAND_QC bits
'0' = Good Quality (main algorithm with or without saturation)
'1' = Other Quality (back-up algorithm or fill values)

1,1 SENSOR
'0' = Terra
'1' = Aqua

2,2 DEADDETECTOR
'0' = Detectors apparently fine for up to 50% of channels 1,2
'1' = Dead detectors caused >50% adjacent detector retrieval

3,4 CLOUDSTATE (this inherited from Aggregate_QC bits {0,1} cloud state)
'00' = 0 Significant clouds NOT present (clear)
'01' = 1 Significant clouds WERE present
'10' = 2 Mixed cloud present on pixel
'11' = 3 Cloud state not defined, assumed clear

5,7 SCF_QC (3-bit, (range '000'..100')) 5 level Confidence Quality score.
'000' = 0, Main (RT) method used, best result possible (no saturation)
'001' = 1, Main (RT) method used with saturation. Good, very usable
'010' = 2, Main (RT) method failed due to bad geometry, empirical algorithm used
'011' = 3, Main (RT) method failed due to problems other than geometry, empirical algorithm used
'100' = 4, Pixel not produced at all, value couldn't be retrieved (possible reasons: bad L1B data, unusable MOD09GA data)

For non-improved NASA's operational MOD16A2, we suggest users at least exclude cloud-contaminated cells. For the improved and reprocessed MOD16A2, users may ignore QC data layer because cloud-contaminated LAI/FPAR gaps have been temporally filled before
calculating ET (Mu et al., 2007, also see previous section 3.2.1 and following 6.3). QC just denotes if filled LAI/FPAR were used as inputs. Because current operational MOD16A2 didn’t calculate ET when the input MODIS data are unreliable, users may also ignore QC data layers for the NASA’s operational MOD16 but just use pixels with values within the valid range.

6.2.2. MOD16A3

Table 6.2 lists science data sets in annual MOD16A3. ET_500m and PET_500m are the summation of total daily ET/PET through the year (0.1 kg/m\(^2\)/year) whereas LE and PLE are the corresponding average total latent energy over a unit area for a unit day (10000 J/m\(^2\)/day) through the year. LE_500m and PLE_500m have the same unit, data type (signed 2-byte short int16), valid range and fill values as those listed above for the 8-day MOD16A2; whereas annual ET_500m and PET_500m are saved in unsigned 2-byte short integer (uint16) with valid range from 0 to 65528.

Similar to MOD16A2, as listed in Table 6.2, for valid data (Valid_data with the valid range) of MOD16A3, the real value (Real_value) of each data set (ET, LE, PET or PLE) in the corresponding units (kg/m\(^2\)/yr or J/m\(^2\)/d) can be calculated using the following equation,

\[
Real\_value = Valid\_data \times Scale\_Factor \tag{27}
\]

Though data attributes list one _FillValue: 65535 in the HDFEOS MOD16A3 file, there are, in fact, 7 fill values as listed below for non-vegetated pixels without ET calculations.

65535 = _Fillvalue
65534 = land cover assigned as perennial salt or Water bodies
65533 = land cover assigned as barren,sparse veg (rock,tundra,desert)
65532 = land cover assigned as perennial snow,ice.
65531 = land cover assigned as "permanent" wetlands/inundated marshland
65530 = land cover assigned as urban/built-up
65529 = land cover assigned as "unclassified" or (not able to determine)

QC data field in annual MOD16A3, ET_QC_500m, is different from most MODIS QC data sets because it is not bitfields but a more meaningful QC assessment for annual composite values. We used the method proposed by Zhao et al. (2005) to define annual ET QC as

\[
ET\_QC\_500m = 100.0 \times \frac{NUg}{Totalg} \tag{28}
\]
where NUg is the number of days during growing season with filled MODIS 500m LAI inputs to MOD16 due to missing or unfavorable atmospheric contaminated MODIS LAI (hence FPAR) if improvement reprocess is employed. Totalg is total number of days in the growing season. The growing season is defined as all days with Tmin above the value where stomata close as in the BPLUT.

The data type of ET_QC_500m is unsigned 1-byte integer (uint8) with valid range from 0 to 100. For vegetated land pixels, if ET_QC_500m has no spatial variations, it will imply the MOD16A3 is the NASA’s operational data product, but not the improved by reprocessing because frequency of cloud contaminations varies with space. Though data attributes list one _FillValue: 255 in the HDFEOS MOD16A3 file, there are, in fact, 7 fill values as listed below for non-vegetated pixels.

255 = _FillValue
254 = land cover assigned as perennial salt or Water bodies
253 = land cover assigned as barren,sparse veg (rock,tundra,desert)
252 = land cover assigned as perennial snow,ice.
251 = land cover assigned as "permanent" wetlands/inundated marshland
250 = land cover assigned as urban/built-up
249 = land cover assigned as "unclassified" or (not able to determine)?

6.3. Evaluation of NASA Operational MOD16 with NTSG Gap-filled

The following subsection 1) reveals the differences between NASA operational and NTSG gap-filled MOD16 by showing one 8-day global browser of ET in Figure 6.1; 2) demonstrates close global agreements between NASA operational Collection6 MOD16A2, MYD16A2 and NTSG Collection5 gap-filled data. Based on our evaluation, we conclude that NASA operational Collection6 MOD16A2 and MYD16A3 are ready for users to apply the data to studies of global terrestrial water and energy cycles and environmental changes.

As mentioned in the previous sections, NASA operational MOD16A2 contains data gaps mainly due to cloudiness or snow cover, which obscures the ground information observed by MODIS and results in unrealistic biophysical variables derived from MODIS, the inputs to MOD16 (Figure 6.1). The reprocessed MOD16 dataset from Numerical Terradynamic Simulation Group (NTSG) at University of Montana (UMT) is a gap-filled dataset which have solved the issue of cloud- or snow-contaminations by temporally gap-filling the biophysical variables using the data from the uncontaminated data prior and post the contaminated periods (Zhao et al., 2005; Mu et al., 2007; Mu et al., 2011).

Figure 6.1 shows an 8-day (2008281, early October) MODIS ET from gap-filled NTSG Collection5 (C5) and operational Collection (C6) NASA MOD16 and MYD16. It clearly shows large areas with data gaps which are mainly caused by cloudiness or snow cover. Currently, fill value denoting “Barren or sparsely vegetated” are used as value for these data gaps with vegetated pixels in operational data set which is shown in bronze color in the image. In tropical rainforests, there are large areas of data gaps caused by cloudiness in the NASA operational
MOD16A2 8-day ET datasets, similar phenomena occur to the other three variables: LE, PET and PLE (not shown). The main reason for more data gaps in MYD16 than in MOD16 is the difference in the local overpass time between TERRA and Aqua satellite. TERRA’s overpass time is in the morning whereas Aqua in the afternoon, and convection is much stronger in the afternoon when the land surface is warmer than in the morning when it is cooler. Stronger convection potentially can induce more cloudiness.

**Figure 6.1.** Comparison of MOD16A2 for an 8-day of 2008281 (Oct 7th through Oct 14th) between NTSG Collection5 gap-filled and NASA operational Collection6 with data gaps due to cloudiness or snow cover.
We evaluated the NASA C6 operational MOD16 by comparing it with gap-filled NTSG C5 just for commonly valid pixels from both data sets. Because C6 and C5 have different versions of MODIS inputs, such as MODIS land cover, LAI/FPAR, and surface albedo, and the two also use different versions of daily meteorological data sets (operational GMAO for NASA and long-term consistent MERRA/GMAO for NTSG), it is expected that the two data sets would have differences. In addition, the C6 has a higher spatial resolution (500m) then the C5 (1-km). We randomly chose year 2008 because it is after year 2002, when a full yearly MODIS datasets are available from either TERRA or Aqua. To perform pixel-by-pixel comparisons, we first smoothed the NASA C6 operational 500m data into 1-km.

We used NTSG gap-filled MOD16 as baseline for the evaluation. We compared all 46 8-day ET, LE, PET and PLE for both MOD16A2 and MYD16A2 and three statistic metrics (mean, STD, and correlation) are used. Mean and TSD can reveal if the two data sets have similar magnitude and range of variations, and correlation can reveal if the two data sets have similar directions of variations. Though there is no gap-filled MYD16A2 from NTSG, we still use NTSG MOD16A2 as baseline to assess NASA operational MYD16A2. We also separated MOD from MYD to have two sets of evaluations in order to maximize the number of valid pixels involved for the assessments. Otherwise, as shown in Figure 6.1, there would be much fewer common valid pixels if we put NASA MOD16 and MYD16 together.

Figure 6.2 shows the seasonality of mean, STD, and correlation for ET, LE, PET and PLE between baseline NTSG MOD16A2 and NASA operational MOD16A2; and between baseline NTSG MOD16A2 and NASA operational MYD16A2, respectively. Correspondingly, Table 6.3 shows the averages of difference ($\bar{Diff}$) in mean, relative differences ($\overline{R_{Diff}}$) in %, and average correlation ($\bar{Cor}$) across all 46 8-days in 2008 between the NASA operational MOD16A2 and MYD16A2 and NTSG MOD16A2, respectively. $\overline{Diff}$ and $\overline{R_{Diff}}$ are defined below,

$$
\bar{Diff} = \frac{\sum_{i=1}^{46} (NASA\ NRT - NTSG)}{46}
$$

$$
\overline{R_{Diff}} = 100 * \frac{\bar{Diff}}{NTSG}
$$

The figures and tables show that both NASA operational C6 MOD16 and MYD16 overall tend to be higher than NTSG gap-filled MOD16. For ET and LE, the relative differences are greater in the extra tropics than the tropics, whereas such tendency is opposite for the PET and PLE. The averages of relative differences for four latitudinal zones are less than 9% and averages of the correlations are around 0.9, suggesting the closeness of NASA operational MOD16A2 to the baseline, NTSG gap-filled MOD16A2.

NTSG C5 MOD16A2 has been validated over eddy flux towers (Mu et al., 2011), and the close agreement in the seasonality between NASA’s operational C5 MOD16A2, MYD16A2 and NTSG data reveals the reasonability (magnitude, range and directions of variations) of NASA operational MOD16A2 and MYD16A2 for valid pixels. Based on our evaluations, we conclude
that NASA operational MOD16A2 and MYD16A2 are ready and useful for users to apply the data to the studies of global terrestrial water and energy cycles and environmental changes.

Table 6.3. A) Averages of difference (\(\text{Diff}^{\overline{\text{}}}\)), relative differences (\(\text{R}_{\text{Diff}}^{\overline{\text{}}}\)) in %, and average correlation (\(\text{Cor}^{\overline{\text{}}}\)) across all 46 8-days in 2008 between the NASA operational and NTSG MOD16A2 by four latitudinal zones.
